The methoxy radical is an intermediate in the atmospheric oxidation of methane, and as the simplest alkoxy species, its behavior is fundamental to understanding the degradation of alkoxy radicals. The temperature-dependent rate constants for methoxy radicals reacting with O₂ have been studied both experimentally and theoretically. However, all previous experiments were carried out at room temperature and above, which may fail to represent the situation in the atmosphere. Furthermore, the mechanism of this fundamental reaction remains uncertain: the fitted experimental Arrhenius equation suggests a small pre-exponential factor (10^{-14} cm³molecule⁻¹s⁻¹), and previous theoretical studies suggest that tunneling effects play a significant role in this reaction. The rate constants of CD₃O (the fully deuterated isotopologue of CH₃O) with O₂ are expected to be much smaller due to zero-point energy effects and the reduced tunneling effect, which may provide insights into the mechanism of the reaction.

Using the FT-IR smog chamber technique, we measured the relative rate constants of CH₃O reacting with O₂ and NO₂ at 250-333 K, as well as the relative rate constants of CD₃O reacting with O₂ and NO₂ at 277-335 K. Applying the IUPAC recommended rate constants of CH₃O and NO₂, the absolute rate constants of CH₃O and CD₃O reacting with O₂ are fitted (see the attached plot) by the Arrhenius expression, giving $k_{\text{CH}_3\text{O}+\text{O}_2} = 1.89_{-0.60}^{+0.89} \times 10^{-14} \exp[-(751 \pm 107)/T]$ cm³molecule⁻¹s⁻¹; $k_{\text{CD}_3\text{O}+\text{O}_2} = 2.58_{-0.98}^{+1.57} \times 10^{-15} \exp[-(667 \pm 145)/T]$ cm³molecule⁻¹s⁻¹, respectively. Over the range 277-333 K, the kinetic isotope effect associated with deuterium substitution is about 5, and not sensitive to temperature.
