As natural gas extraction and use continue to increase, the need to quantify methane (CH₄) emissions, a powerful greenhouse gas (GHG), has grown. Large discrepancies in Indianapolis CH₄ emissions are observed when comparing inventory, aircraft mass-balance, and tower inverse CH₄ emissions estimates. The Indianapolis Flux Experiment (INFLUX) tower network is utilized to investigate these discrepancies between bottom-up and top-down CH₄ emission assessments. The INFLUX network includes 9 towers currently hosting continuous, highly-calibrated CH₄ mole fraction measurements to examine the temporal variability in 2012-2016 CH₄ at Indianapolis (see Figure). Three major reasons that may be responsible for the above-mentioned discrepancy are identified: (1) a highly-variable and spatially non-uniform U.S. continental CH₄ background with changes up to 150 ppbv, (2) temporal variability in anthropogenic urban CH₄ sources and (3) an influence of unknown CH₄ sources. To address the first issue, we propose a method for identifying the days with a regionally uniform CH₄ background. With regard to the second issue, we recommend temporal consistency when aircraft mass-balance and tower inverse methods are compared. For the third concern, we investigate the ways to approximate the impact of the unknown sources on the CH₄ flux estimates. Work continues to quantify the implications for total city CH₄ emissions given the regional and local CH₄ temporal variability.

Figure 1. CH₄ enhancements (calculated by subtracting CH₄ background from the tower measurements) using 1500-2200 UTC data for the full year of 2015 as measured by the INFLUX tower network. Bivariate polar plots show CH₄ enhancements as a function of wind direction (degrees) and wind speed (m/s).
